This data can be loaded using the following code.

```
library(tidyverse)
currentDataset <- read_csv("https://statsnotebook.io/blog/data_
management/example_data/APC_cannabis.csv")
```

Supposed that the data was collected every three years between 2001 and 2019, there were 7 repeated cross-sectional surveys.

In this dataset, there are 8 variables.

1. Sex - 1: Male; 2: Female
2. HighSchool - 0: Not completed high school; 1: completed high school
3. remoteness - 1: Major cities; 2: Inner regional area; 3: Remote area
4. Year - Year the data was collected: 2001/2004/2007/2010/2013/2016/2019
5. cohort_cat - Birth cohort: 1: 1941/50; 2: 1951/60; 3: 1961/70; 4: 1971/80; 5: 1981/90; 6: 1991/2000
6. weekly_cannabis - Weekly cannabis use: 0: No; 1: Yes
7. AgeR - Recoded age. The value is calculated by dividing the actual age by 10. This is to facilitate model converence when we add the quadratic term of age into the model.

Sex	HighSch...	remoten...	Year	cohort_cat	weekly_c...	AgeR
1	1	1	2019	6	0	2.2
1	0	1	2019	1	0	6.9
2	1	1	2019	6	0	2.5
2	0	1	2019	4	0	4.3
2	1	2	2019	6	0	2.8
1	1	2	2019	3	0	5.5
2	1	2	2019	4	0	4.7
1	0	2	2019	1	0	7.1
1	0	2	2019	3	0	5.1
1	1	1	2019	2	0	6.6
1	1	1	2019	6	0	2.6
2	1	1	2019	4	0	4.8

Age-Period-Cohort model

In this example, we will test the age, period and cohort effect on weekly cannabis use. Since weekly cannabis use is a dichotomized variable (Yes/No), we will firstly fit a mixed effects (multilevel level) logistic model

At level 1, we have

$logit$ P(cannabis$_{ijk}$) = b$_{0jk}$+b$_1$Age$_{ijk}$+b$_2$Age$^2_{ijk}$+b$_3$Female$_{ijk}$+b$_4$Inner regional$_{ijk}$+b$_5$Remote area$_{ijk}$+b$_6$High School$_{ijk}$

where *Female*, *Inner regional*, *Remote area* and *High School* are indicator variables (i.e. *High School* = 0 for participants who haven't finished high school and *High School* = 1 for participants who finished high school). R will automatically create these indicator variables when a

categorical/factor variable is entered into a model. The quadratic term of age is included to capture the potential quadratic effect of age.

At level 2, we have

$$b_{0jk} = \gamma_0 + u_{0j} + v_{0k}$$

where u_{0j} and v_{0k} represents the effect of being in period j and birth cohort k, and $u_{0j} \sim N(0, \tau_u)$ and $v_{0j} \sim N(0, \tau_v)$. The u_{0j} and v_{0k} have also been referred to as the random effect of period and cohort. It should be noted that the index ijk is the index for individual i in period j and cohort k.

APC analysis in StatsNotebook

In this analysis, after loading the data, we will need to

1. convert the variable *Sex*, *HighSchool*, *remoteness*, *Year*, and *cohort_cat* into factor variables;
2. centre the age variable at 2 so that the intercept of the model represented the effect of age at 20 years old (i.e. substracting 2 from the age variable); and
3. create the quadratic term of age, *AgeR2*.

**See Converting variable type and Converting variable type for a step-by-step guide.

```
#Converting Sex, HighSchool, Year, cohort_cat and remoteness into
factor variable
currentDataset$Sex <- factor(currentDataset$Sex, exclude = c("", NA))
currentDataset$HighSchool <- factor(currentDataset$HighSchool, exclude
= c("", NA))
currentDataset$Year <- factor(currentDataset$Year, exclude = c("", NA))
currentDataset$cohort_cat <- factor(currentDataset$cohort_cat, exclude
= c("", NA))
currentDataset$remoteness <- factor(currentDataset$remoteness, exclude
= c("", NA))

#centre age at 20 years old and create the quadratic term
currentDataset$AgeR = currentDataset$AgeR - 2
currentDataset$AgeR2 = currentDataset$AgeR^2
```

To fit a Age-Period-Cohort model,

1. Click **Analysis** at the top
2. Click **Regression** and select **Logistic Regression (Binary outcome)** from the menu
3. In the left panel, select *weekly_cannabis* into *outcome*, *AgeR*, *AgeR2* (the newly created quadratic term of *AgeR*), *Sex*, *HighSchool* and *remoteness* into *Covariates*, and select *cohort_cat* and *Year* into *Random Effect*.
4. Click **Code and Run**

R codes explained

The Age-Period-Cohort model in this example is a mixed effects logistic model with random
intercepts. The following are from the top section of the generated codes. The analysis uses the
`glmer` function from the `lme4` library to fit the model, the `summary` function to display the model
output, and then the `confint` function to compute the confidence intervals of the parameters

using the Wald's method.

```
library(lme4)

res <- glmer(weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool + (1 | cohort_cat) + (1 | Year),
  family = binomial,
  data = currentDataset)
summary(res)
confint(res, level = 0.95, method = "Wald")
```

The next section of the codes extracts the variance-covariance matrix of the parameters, and calculate the odds ratio and the corresponding confidence intervals of each variable.

```
se <- sqrt(diag(vcov(res)))
z <- -qnorm((1-0.95)/2)
exp(cbind(Est=fixef(res),
  "2.5%"  = fixef(res) - z*se,
  "97.5%" = fixef(res) + z*se))
```

The following are excerpt of outputs from the above codes.

```
Fixed effects:
             Estimate Std. Error z value Pr(>|z|)
(Intercept) -1.47823    0.19175  -7.709 1.27e-14 ***
AgeR        -0.49014    0.06268  -7.819 5.32e-15 ***
AgeR2        0.01221    0.01186   1.030    0.303
Sex2        -0.84691    0.03172 -26.697  < 2e-16 ***
remoteness2  0.14050    0.03362   4.179 2.93e-05 ***
remoteness3  0.30242    0.05130   5.895 3.74e-09 ***
HighSchool1 -0.85670    0.03230 -26.521  < 2e-16 ***
```

The following are odds ratio calculated by exponentiating the model parameters.

```
                  Est       2.5%      97.5%
(Intercept) 0.2280404 0.1566014 0.3320687
AgeR        0.6125418 0.5417249 0.6926162
AgeR2       1.0122856 0.9890264 1.0360917
Sex2        0.4287377 0.4028924 0.4562409
remoteness2 1.1508512 1.0774569 1.2292450

HighSchool1 0.4245599 0.3985133 0.4523089
```

As expected, age is strongly associated with reduced odds of using cannabis weekly. The quadratic term of age is not statistically significant and is very close to zero.

In the presence of the quadratic term of age and other variables in the model, to better understand the effect of age on cannabis use, we can use the `emmeans` package to calculate the probability of weekly cannabis use with the following codes.

```
library(emmeans)

Age_eff = data.frame()
```

```
# Age is centred at 20 years old, and is divided by 10.
# (i.e. 0 means the participant is 20 years old, 1 means 30 years old,
etc)
# We use a for loop to calculate the probability of weekly cannabis use
# when the age "score" is between 0 and 5, with 0.5 increment.
# The calculated probability is stored in a new data frame Age_eff

for (i in 0:10) {
  emm <- emmeans(res,  ~ AgeR + AgeR2,
  at = list(
  AgeR = i/2, AgeR2 = (i/2)^2), type = "response", level = 0.95)
  Age_eff = rbind(data.frame(summary(emm)), Age_eff)
}
```

The above codes prodce the following output. This can be considered as the "average" probability averaging across other variables. Note that a score of "0" for age represents 20 years old and a score of "5" represents 70 years old. The column *prob* is the estimated probability of weekly cannabis use averaged across levels of sex, remoteness, and high school completion.

```
     AgeR AgeR2        prob          SE  df    asymp.LCL  asymp.UCL

```

We can use the `ggplot2` library to visualise the age effect using the following codes. See our Data Visualisation guide for tutorials about using `ggplot2`.

```
#We transformed back the x axis from "age score" into actual age by
adding 2 and then multiplying by 10.
plot <- ggplot(Age_eff, aes(x = ((AgeR+2)*10), y = prob)) +
    geom_point() +
    geom_line() +
    geom_errorbar(aes(ymin = asymp.LCL, ymax = asymp.UCL), width = 1) +
    xlab("Age") +
    ylab("Probability of weeky cannabis use")

plot
```
Testing the joint cohort and period effect

To test the joint cohort and period effect, we save the current model into a new variable `res_cohort_period` using the following codes.

```
res_cohort_period <- res
```

We then rerun the model without the cohort and period effect (i.e. removing the random effect of cohort and period). This can be done by removing the *cohort_cat* and *year* from random effect in **StatsNotebook**'s menu or by changing the previous codes. The function `glm` will be used instead of `glmer`

```
library(lme4)

res <- glm(weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool,
   family = binomial,
   data = currentDataset)
summary(res)
confint(res, level = 0.95, method = "Wald")
```

The above codes can be used to run the analysis without both cohort and period effect. To test the joint cohort and period effect, we can use a likelihood ratio test comparing both models using the `anova` function.

```
anova(res_cohort_period, res)
```

This produces the output below. These results indicate that the model with cohort and period effect fits the data significantly better than the model without, indicating that at least one of the cohort or period effect is significantly different from zero.

```
Data: currentDataset
Models:
res: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness + HighSchool
res_cohort_period: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool +
res_cohort_period:     (1 | cohort_cat) + (1 | Year)
                 npar   AIC    BIC logLik deviance Chisq Df Pr(>Chisq)
res                 7 34069 34136 -17028    34055
res_cohort_period   9 33929 34014 -16956    33911 144.2  2  < 2.2e-16
***
---
Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

Testing the cohort effect

We can also test the cohort or period effect individually. For example, we can test the cohort effect by running a model with only period effect, and compare this model with the model with both cohort and period effect. The following is generated by removing *cohort_cat* from the random effect in **StatsNotebook**'s menu. We save the model output to the variable *res_period* instead of the default *res*.

```
res <- glmer(weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool + (1 | Year),
  family = binomial,
  data = currentDataset)
summary(res)
confint(res, level = 0.95, method = "Wald")

#We add the line of codes to save the model result to the variable
res_period
res_period <- res
```

Similarly, we use the `anova` function to compare the model with both cohort and period effect and the model with only period effect.

```
anova(res_cohort_period, res_period)
```

This test produces the following results. The model with both cohort and period effect fits the data significantly better than the model with only period effect. This indicates that the cohort effect is significantly different from zero.

```
Data: currentDataset
Models:
res_period: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool +
res_period:      (1 | Year)
res_cohort_period: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool +
res_cohort_period:      (1 | cohort_cat) + (1 | Year)
                  npar   AIC   BIC logLik deviance  Chisq Df Pr(>Chisq)
res_period           8 34049 34125 -17016    34033
res_cohort_period    9 33929 34014 -16956    33911 121.81  1  < 2.2e-16
***
---
Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

Testing the period effect

The period effect can be tested similiarly by comparing the model with both cohort and period effect against the model with only the cohort effect with the following codes.

```
library(lme4)

res <- glmer(weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool + (1 | cohort_cat),
  family = binomial,
  data = currentDataset)
summary(res)
confint(res, level = 0.95, method = "Wald")

res_cohort <- res

anova(res_cohort_period, res_cohort)
```

These codes produce the following results, which indicates that the period effect is also significantly different from zero.

```
Data: currentDataset
Models:
res_cohort: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool +
res_cohort:      (1 | cohort_cat)
res_cohort_period: weekly_cannabis ~ AgeR + AgeR2 + Sex + remoteness +
HighSchool +
res_cohort_period:      (1 | cohort_cat) + (1 |cyw195510  Year)
                  npar   AIC   BIC logLik deviance  Chisq Df Pr(>Chisq)
res_cohort           8 33950 34026 -16967    33934
res_cohort_period    9 33929 34014 -16956    33911 23.093  1  1.543e-06
***
---
Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
```

Visualising the cohort effect

Now that we know there are cohort and period effect on weekly cannabis use. We can visualise both effects. Suppose that we have stored the results from the model with both cohort and period effect into the variable `res_cohort_period`. We can use the `ranef` function to extract the random effect components, the cohort and period effect, from this model.

```
#Extract the random effect
u0 <- ranef(res_cohort_period, condVar = TRUE)
names(u0$Year) <- "est"
names(u0$cohort_cat) <- "est"

#Extract the standard error
period_eff <- data.frame(est = u0$Year, se = sqrt(attr(u0[[1]],
"postVar")[1, ,]),
  period = c(2001, 2004, 2007, 2010, 2013, 2016, 2019))
cohort_eff <- data.frame(est = u0$cohort_cat, se = sqrt(attr(u0[[2]],
"postVar")[1, ,]),
  cohort = c("1941/50","1951/60","1961/70","1971/80","1981/90","1991/
2000"))

period_eff$upper <- period_eff$est + 1.96*period_eff$se
period_eff$lower <- period_eff$est - 1.96*period_eff$se
cohort_eff$upper <- cohort_eff$est + 1.96*cohort_eff$se
cohort_eff$lower <- cohort_eff$est - 1.96*cohort_eff$se

#Visualise the period and cohort effect using ggplot2
plot <- ggplot(period_eff, aes(x = period, y = est)) +
  geom_point() +
  geom_errorbar(aes(ymin = lower, ymax = upper), width = .2) +
  xlab("Year") +
  ylab("Conditional log odds of the period effect")

plot

plot <- ggplot(cohort_eff, aes(x = cohort, y = est)) +
  geom_point() +
  geom_errorbar(aes(ymin = lower, ymax = upper), width = .2) +
  xlab("Year") +
  ylab("Conditional log odds of the cohort effect")

plot
```
